Module 3, Part 1: Generalized Linear Models

BIOS 526

1/52 M3: GLMs

Concepts

- Link function.
- Logistic regression and odds ratio. BINARY
- Probit regression. BINARY (diff link function)
- Poisson regression. COUNT

Readings

- Chapter 3, Wood, S. *Generalized Additive Models*, 2017. Has a nice, self-contained introduction to generalized linear models.

2/52 M3: GLMs

Linear Regression Model

Consider the following multiple linear regression model. For $i = 1, \ldots, n$,

$$y_i = \beta_0 + \sum_{k=1}^{p} \beta_k x_{ik} + \epsilon_i \qquad \epsilon_i \overset{iid}{\sim} N(0, \sigma^2),$$

where x_{ik} is the kth linear predictor for observation i.

The above model assumes

- $\beta_0, \beta_1, \ldots, \beta_p$ are fixed unknown constants;
- only the residual error ϵ_i is random.

Therefore,

1. y_i follows a normal distribution.
2. $E[y_i \,|\, \boldsymbol{x}_i] = \beta_0 + \sum_{k=1}^{p} \beta_k x_{ik}$.

The linear regression part is used to model only the mean function of y_i.

3/52 M3: GLMs

Generalized Linear Regression Model

A generalized linear model (GLM) extends linear regression to other distributions, where the response variable is generated from a distribution in the exponential family.

A GLM involves three ingredients:

1. An exponential family of probability distributions.
2. A linear model $x_i'\beta$.
3. A link function $g()$ and its inverse $g^{-1}()$ relates the linear model to its expectation:

$$E[y_i \,|\, x_i] = \mu_i = g^{-1}(x_i'\beta)$$
$$Var[y_i \,|\, x_i] = V(\mu_i) = V(g^{-1}(x_i'\beta))$$

Note: unlike ordinary least squares, the basic form of the GLM does not involve a noise variance (no σ^2).

Exponential Family

The basic form for an exponential family density is

$$f_\theta(y) = \exp\left[\{y\theta - b(\theta)\}/a(\phi) + c(y,\phi)\right],$$

where b, a, and c are known functions, and ϕ is a known scale parameter. There is only one unknown parameter: θ.

↳ this is the part that doesn't generalize e.g. in normal linear model, known σ^2

In the GLM, θ will be a function of $x_i'\beta$.

Examples of distributions in the exponential family include: normal distribution with **known** variance (link = identity), Bernoulli (logit or probit link), binomial (with fixed number of trials), gamma, exponential (link: negative inverse), and others.

↳ binomial, # trials = 1 → if we input $x_i'\beta$ we get $x_i'\beta$ aka same thing

https://en.wikipedia.org/wiki/Generalized_linear_model

Rather than derive expressions for the general case, we will focus on the two most popular models:

1. Binary outcome: $y_i \overset{ind}{\sim}$ Bernoulli (p_i), where p_i is the probability of success.
2. Poisson outcome: $y_i \overset{ind}{\sim}$ Poisson (λ_i), λ_i is the rate parameter, equal to expected number of events.

GLMs

The mean and variance function of y_i can be expressed as a function of the distribution parameters (i.e. p_i for Bernoulli and λ_i for Poisson).

1. Binary outcome:
   $E[y_i] = \mu_i = p_i$,
   $Var[y_i] = V[\mu_i] = V[p_i] = p_i(1-p_i)$.
2. Poisson outcome:
   $E[y_i] = \mu_i = \lambda_i$,
   $Var[y_i] = V[\mu_i] = V[\lambda_i] = \lambda_i$. ← mean = variance

A natural approach is to model the mean as a function of linear predictors. A difficulty in modeling non-normal data is that the distributional parameters often have constraints.

1. Binary outcome has expected value $p_i \in (0,1)$
2. Poisson outcome has expected value $\lambda_i > 0$.

Derivation:

$\text{Var}(y_i) = E[y_i - E(y_i)]^2$

to continuous...

$= \sum_{m=0}^{1} [m - E(y_i)]^2 P(y_i = m)$

$= (0-p_i)^2(1-p_i) + (1-p_i)^2 p_i$

$= (1-p_i)(p_i^2 + (1-p_i)p_i)$

$= (1-p_i)(p_i)$

Workspace

Workspace

Generalized Linear Regression Model

Our solution is to model the transformed mean function:

we have p+1 parameters

$$g(\mu_i) = \beta_0 + \sum_{k=1}^{p} \beta_k x_{ik}.$$

$E[y_i|x_i]$

The function $g(\cdot)$ is known as the link function.

The link function should have some desirable properties:

1. $g(\cdot)$ should have a range of $(-\infty, \infty)$ because β_k and x_{ik} can take any real value.
2. $g(\cdot)$ should have a domain that corresponds to possible values of μ_i. (i.e. $(0, 1)$ for binary outcome and $(0, \infty)$ for Poisson outcome.
3. $g(\cdot)$ should be 1-to-1. Then,

$$\mu_i = g^{-1}(\beta_0 + \sum_{k=1}^{p} \beta_k x_{ik}).$$

A strictly increasing or decreasing function will satisfy this.

"Both of my shoes are untied"
-Ben Risk
9/18

GLM for Binary Outcome

For $i = 1, \ldots, n$, assume

$$y_i \overset{ind}{\sim} \text{Bernoulli } (p_i),$$

where $y_i \in \{0, 1\}$, $y_i|p_i$ for $i = 1, \ldots, n$ are independent, and p_i is the probability $y_i = 1$. The probability mass function is given by

$$f(y_i|p_i) = p_i^{y_i}(1 - p_i)^{1-y_i}.$$

We know that

$$\mu_i = p_i = P(Y_i = 1).$$

So we wish to model

link function of this probability

$$g[P(Y_i = 1)] = \beta_0 + \sum_{k=1}^{p} \beta_k x_{ik}.$$

The two most commonly used link functions are the logistic function and the probit function.

Logistic Regression

The logistic regression is formulated as follows. For $i = 1, \ldots, n$,

$$y_i \overset{ind}{\sim} \text{Bernoulli}\,(p_i)$$

$$\log\left(\frac{p_i}{1-p_i}\right) = \beta_0 + \sum_{k=1}^{p} \beta_k x_{ik}.$$

- $g(\mu_i)$ is the log odds of success probability.
- $\log\left(\frac{p_i}{1-p_i}\right) \to -\infty$ when $p_i \to 0$; and $\log\left(\frac{p_i}{1-p_i}\right) \to \infty$ when $p_i \to 1$
- $\log\left(\frac{p_i}{1-p_i}\right)$ is strictly increasing.

not IID but just independent. They have diff. probabilities of success

$E[y_i]$ aka $E[y_i]$

something's happening here's slapping

$g(p_i)$

$\frac{p_i}{1-p_i}$ = the odds

$p_i < p_i'$, $g(p_i) < g(p_i')$

NO ERROR TERM ε why?

10/52 M3: GLMs

Likelihood function: logistic regression

Bernoulli version

$\log \prod$ turns into $\sum \log \ldots$ when a failure is observed

$$\ell(\beta; \mathbf{y}, \boldsymbol{x}) = \log \prod_{i=1}^{n} p_i^{y_i}(1-p_i)^{1-y_i} = \sum_{i=1}^{n} y_i \log p_i + (1-y_i)\log(1-p_i)$$

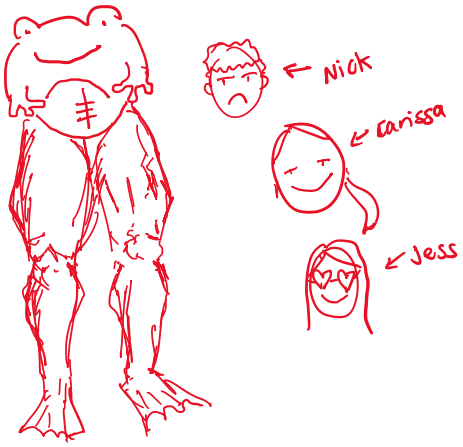
where $p_i = \frac{e^{x_i'\beta}}{1+e^{x_i'\beta}}$ logistic function

$$= \sum_{i=1}^{n} y_i \log\left(\frac{e^{\beta' \boldsymbol{x}_i}}{1+e^{\beta' \boldsymbol{x}_i}}\right) + (1-y_i)\log\left(\frac{1}{1+e^{\beta' \boldsymbol{x}_i}}\right)$$

$$= \sum_{i=1}^{n} y_i \beta' \boldsymbol{x}_i - \log(1+\exp(\beta' \boldsymbol{x}_i))$$

In practice, GLMs are estimated using iteratively reweighted least squares. We won't go into details, but see p. 107 in Wood for more info.

11/52 M3: GLMs

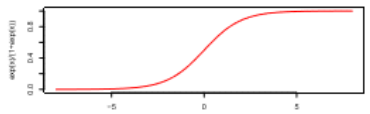


more general than logistic regression

The logistic function:

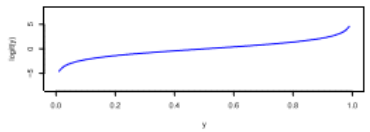
$p(g) = \exp(g)/(1+\exp(g)) = 1/(1+\exp(-g)),\ (-\infty, \infty) \to (0,1).$

MEMORIZE



$\in (0,1)$ $\in (-\infty, \infty)$

The logit function: $g(p) = \log(p/(1-p)),\ (0,1) \to (-\infty, \infty).$



12/52 M3: GLMs

$$g(p) = \log\left(\frac{p}{1-p}\right)$$

$$e^{g(p)} = \frac{p}{1-p}$$

$$e^{g(p)}(1-p) = p$$

$$e^{g(p)} - p e^{g(p)} = p$$

$$e^{g(p)} = p + p e^{g(p)}$$

$$= p(1 + e^{g(p)})$$

$$p = \frac{e^{g(p)}}{1+e^{g(p)}}$$

Logistic Regression: Interpretation

Consider a simple logistic model with only one predictor:

$$y_i \overset{ind}{\sim} \text{Bernoulli}\ (p_i)$$

$$\log\left(\frac{p_i}{1-p_i}\right) = \beta_0 + \beta_1 x_i.$$

When $x_i = 0$:

- $\log\left(\frac{p_i}{1-p_i}\right) = \beta_0$. i.e. when $x=0$
- β_0 is interpreted as the baseline log odds.
  Function of the probability of success at baseline:

$$p_i = \frac{e^{\beta_0}}{1+e^{\beta_0}}.$$

- Note that the above function satisfies
  - $p_i \in (0,1)$ for $\beta_0 \in \mathbf{R}$.
  - p_i a strictly increasing function of β_0 .

Logistic Regression: Log odds and log odds ratio

Now we consider the effect of a unit change in x_i:

$$\log\left(\frac{p_i}{1-p_i}\right) = \beta_0 + \beta_1 x_i \quad \text{versus} \quad \log\left(\frac{p_i^*}{1-p_i^*}\right) = \beta_0 + \beta_1(x_i+1).$$

Then,

$$\log\left(\frac{p_i^*}{1-p_i^*}\right) - \log\left(\frac{p_i}{1-p_i}\right) = \beta_0 + \beta_1(x_i+1) - (\beta_0 + \beta_1 x_i)$$
$$= \beta_1.$$

In words: β_1 is the change in log odds per unit change in x_i.
Equivalently, it is the log odds ratio per unit change in x_i:

$$\beta_1 = \log\left[\frac{p_i^*/(1-p_i^*)}{p_i/(1-p_i)}\right].$$

Logistic Regression: Odds ratio

INTERPRETATION

e^{β_1} is the odds ratio:

$$e^{\beta_1} = \frac{p_i^*/(1-p_i^*)}{p_i/(1-p_i)}.$$

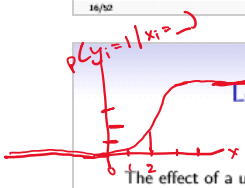
Odds ratio interpretation helpful for indicator variables. Let $x_i = 1$ in exposed group, $x_i = 0$ in unexposed group. Then:

$$e^{\beta_1} = \frac{\left\{\frac{P(y_i=1|x_i=1)}{P(y_i=0|x_i=1)}\right\}}{\left\{\frac{P(y_i=1|x_i=0)}{P(y_i=0|x_i=0)}\right\}} \rightarrow \frac{\text{odds of pre-term birth if smoker}}{\text{odds of pre-term birth if not smoker}}$$
$$= \text{odds(Exposed)/odds(Unexposed)}.$$

e.g. $x_i = 1$ if mother is smoker
$= 0$ " " is NOT a smoker

Logistic Regression: Background

- Logistic regression is commonly used because the slope coefficient corresponds to the log odds ratio (OR), a commonly used measure in epidemiology.
- OR is different from relative risk.
- Risk ratio (RR) is $P(y_i = 1|x_i = 1)/P(y_i = 1|x_i = 0)$
- OR is close to RR when the event $y_i = 1$ is rare, but in general, you need a different model to estimate RR.
- OR can be used in retrospective and observational studies.



Logistic Regression: Probability

The effect of a unit change in x_i depends on x_i on the probability scale.

E.g., $\beta_0 = 0$ and $\beta_1 = 2$:

$$\frac{e^{2(0+1)}}{1+e^{2(0+1)}} - \frac{e^{2(0)}}{1+e^{2(0)}} \neq \frac{e^{2(1+1)}}{1+e^{2(1+1)}} - \frac{e^{2(1)}}{1+e^{2(1)}}$$

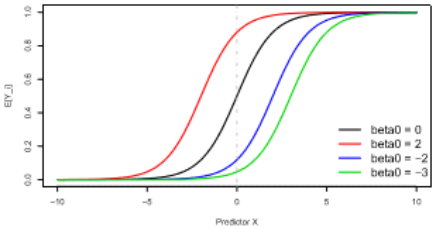
A change in x_i from 0 to 1 increases the probability by 0.38, but a change in x_i from 1 to 2 increases the probability by 0.10.

Intuitively, this has to be the case in order for the probability to max out at 1: $\frac{e^{2(100+1)}}{1+e^{2(100+1)}} - \frac{e^{2(100)}}{1+e^{2(100)}} \approx 1 - 1$.

Logistic Regression: Effects of Baseline Odds

$$\text{logit}(p_i) = \beta_0 + x_i.$$

$$\mu_i = P(Y_i = 1) = \frac{e^{\beta_0 + x_i}}{1 + e^{\beta_0 + x_i}}.$$



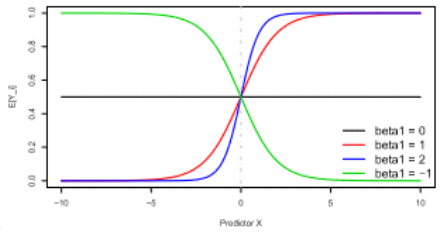
Note:

- The shape is maintained.
- The baseline (intercept) probability changes.

Logistic Regression: Effects of Slope

$$\text{logit}(\mu_i) = \beta_1 x_i.$$

$$\mu_i = P(Y_i = 1) = \frac{e^{\beta_1 x_i}}{1 + e^{\beta_1 x_i}}.$$



Note:

- How the steepness changes.
- How the direction of effect changes.

Logistic Regression: Interpretation

In multiple logistic regression, for $i = 1, \ldots, n$,

$$y_i \overset{ind}{\sim} \text{Bernoulli}\ (p_i) = \text{Bernoulli}\ (\mu_i)$$

$$\log\left(\frac{p_i}{1-p_i}\right) = \beta_0 + \sum_{k=1}^{p} \beta_k x_{ik}.$$

again NO EPSILON ε

- β_0 is the log odds when all covariate values equal zero.
- β_k is the log odds ratio associated with covariate k while controlling for other covariates.

Logistic Regression: Interpretation

The estimated (predicted) value is given by

$$\mu_i = p_i = \frac{e^{\beta_0 + \sum_{k=1}^{p} \beta_k x_{ik}}}{1 + e^{\beta_0 + \sum_{k=1}^{p} \beta_k x_{ik}}}$$

Again, the above function is non-linear in x_k, in contrast with normal regression

Inference: Likelihood Ratio Tests

To conduct inference, we appeal to asymptotic results that hold for large-ish n. There are two approaches:

1) Likelihood Ratio Tests (Difference in Deviance)

-2 log likelihood

full model

Let $\boldsymbol{\beta}_F$ be a vector of coefficients of interest. Then to test $H_0 : \boldsymbol{\beta}_F = 0$, we create a full and reduced model. Let $\ell(\hat{\boldsymbol{\beta}}_{\text{Full}})$ be the log-likelihood of the full model, and $\ell(\hat{\boldsymbol{\beta}}_{\text{Reduced}})$ be the LL for the reduced model. Then we reject H_0 if

$$-2\left\{\ell(\hat{\boldsymbol{\beta}}_{\text{Reduced}}) - \ell(\hat{\boldsymbol{\beta}}_{\text{Full}})\right\} > \chi^2_{\nu,1-\alpha}$$

where ν is the difference in the number of parameters between the full and reduced, and $\chi^2_{\nu,1-\alpha}$ is the critical value from a chi-squared distribution with ν degrees of freedom

Inference: Likelihood Ratio Tests

To conduct inference, we appeal to asymptotic results that hold for large-ish n. There are two approaches:

1) Likelihood Ratio Tests (Difference in Deviance)

Let $\boldsymbol{\beta}_F$ be a vector of coefficients of interest. Then to test $H_0 : \boldsymbol{\beta}_F = 0$, we create a full and reduced model. Let $\ell(\hat{\boldsymbol{\beta}}_{\text{Full}})$ be the log-likelihood of the full model, and $\ell(\hat{\boldsymbol{\beta}}_{\text{Reduced}})$ be the LL for the reduced model. Then we reject H_0 if

$$-2\left\{\ell(\hat{\boldsymbol{\beta}}_{\text{Reduced}}) - \ell(\hat{\boldsymbol{\beta}}_{\text{Full}})\right\} > \chi^2_{\nu,1-\alpha}$$

where ν is the difference in the number of parameters between the full and reduced, and $\chi^2_{\nu,1-\alpha}$ is the critical value from a chi-squared distribution with ν degrees of freedom.

Inference: Wald Tests

2) Wald Tests. Under regularity conditions, asymptotically,

$$\hat{\boldsymbol{\beta}} \sim N(\boldsymbol{\beta}, I(\boldsymbol{\beta})^{-1}),$$

$$I(\boldsymbol{\beta}) = E\left\{\left(\frac{\partial \ell}{\partial \boldsymbol{\beta}}\right)\left(\frac{\partial \ell}{\partial \boldsymbol{\beta}}\right)'\right\} = -E\frac{\partial^2 \ell}{\partial \boldsymbol{\beta}\partial \boldsymbol{\beta}'},$$

where the Hessian $I(\boldsymbol{\beta})$ is called the Fisher information matrix. See Wood p. 106 for details of the expected Hessian which is calculated during iteratively re-weighted least squares.

We can write $\hat{\boldsymbol{\beta}} \sim N(\boldsymbol{\beta}, (\mathbf{X'WX})^{-1}\phi)$ where $\mathbf{W}$ contains the "Fisher weights" and $\phi = 1$ in the usual (not overdispersed) GLM.

In R, the default `summary(glmmodel)` is a Wald-type test: $\hat{\beta}_j / se(\hat{\beta}_j)$, where $se(\hat{\beta}_j)$ is extracted from the square root of the jth diagonal of the above covariance.

"Only one of my shoes is untied today"
– Ben Risk 9/20

Binary Outcome Example

Dataset: a cohort of live births from Georgia born in the year 2001 (N = 77,340).

Variables:

- *ptb*: indicator for whether the baby from pregnancy i was born preterm (< 37 weeks).
- *age*: the mother's age at delivery (centered at age 25).
- *male*: indicator of the baby's sex (1 = male; 0=female).
- *tobacco*: indicator for mother's tobacco use during pregnancy (1 = yes; 0 = no)

"I wanna look at marijuana"
9/20 on this study

The *glm ( )* Function

Fitting a GLM model in R is very similar to a linear regression model. We need to specify the distribution (binomial) and the link function (logit).

```
glm(formula = ptb ~ age + male + tobacco, family = binomial(link = "logit"),
    data = dat)

Deviance Residuals:
    Min      1Q  Median      3Q     Max
-0.5160  -0.4236  -0.4103  -0.4088   2.2500

Coefficients:
             Estimate Std. Error  z value Pr(>|z|)

```

likelihood

if you don't put this, it will default to gaussian

25/52 M3: GLMs

Birth Outcome Analysis

- Preterm delivery was significantly associated with male babies (p-value= 0.005) when controlling for age and mother's smoking status. The odds ratio of a preterm birth for a male baby versus a female baby was 1.07 (95% CI: 1.02, 1.13).
  $OR = e^{0.0723} = 1.07$
  $CI = e^{(0.0723 \pm 1.96*0.0258)} = (1.02, 1.13)$
- Note: transform the intervals. Do NOT transform standard errors (requires delta method).
- Preterm delivery was significantly associated with whether the mother smoked during pregnancy ($p < 0.001$) when controlling for age and the baby's sex. The odds ratio for mother's that smoked versus did not smoke was $e^{0.409} = 1.51$ (95% CI: 1.36, 1.67).

The correct way:

transform the interval

$e^{0.409 \pm 1.96(0.053)}$

>1 means harmful

$e^{0.075} \pm 1.96\, e^{0.025}$ ← WRONG!!

26/52 M3: GLMs

A note about transforming intervals:

For a monotonic ↑ function,

$P(\underbrace{\hat{\beta}_{0.025}}_{\text{lower CI}} \le x) = 0.025$

then

$P(e^{\hat{\beta}_{0.025}} \le e^{x}) = 0.025$

You can also use Delta method

For this class we don't use

$\widehat{Var}(g(\hat{\beta})) \approx (g'(\hat{\beta}))^2 \widehat{var}(\hat{\beta})$

but it is valid

CAN'T TRANSFORM $\widehat{Var}(\hat{\beta})$ i.e. $e^{\hat{\beta}} \pm 1.96\, e^{\widehat{SE}}$ IS INCORRECT

Birth outcome analysis, cont.

M3_part1_GLM. R for fitting binary data?

- The baseline proportion (female babies born to mother of age 25 who didn't smoke) of preterm delivery was

$$\frac{e^{-2.437}}{1+e^{-2.437}} = 0.080.$$

- We didn't find an effect of mother's age.

27/52 M3: GLMs

Birth Outcome Analysis - Mother's Age

We assumed that the mother's age has a linear effect on log odds of preterm birth. Is this a reasonable assumption?

Explore this by calculating % preterm births for each age group.

30/52 M3: GLMs

Probit Regression

Probit regression is an alternative approach to model binary data. It still assumes the Bernoulli model, but uses a different link function. For $i = 1, \ldots, n$,

$$y_i \overset{ind}{\sim} \text{Bernoulli}\ (p_i)$$

$E(y_i)$

$$\Phi^{-1}(p_i) = \beta_0 + \sum_{k=1}^{p} \beta_k x_{ik},$$

inverse CDF instead of logistics

where Φ^{-1} is the inverse cumulative distribution function of a standard normal distribution. Recall $\Phi^{-1}(x)$ asks what Z-value gives a cumulative probability of x?

- Example: $\Phi^{-1}(0.5) = 0$ and $\Phi^{-1}(0.975) = 1.96$.
- Note $\Phi^{-1}(p_i)$ is strictly increasing, has range $(-\infty, \infty)$ and domain

Probit will NOT be on EXAM

normal distribution. Recall $\Phi^{-1}(x)$ asks what Z-value gives a cumulative probability of x?

- Example: $\Phi^{-1}(0.5) = 0$ and $\Phi^{-1}(0.975) = 1.96$.
- Note $\Phi^{-1}(p_i)$ is strictly increasing, has range $(-\infty, \infty)$ and domain $(0, 1)$.

31/52 M3: GLMs

Probit Regression

Φ for pnorm in "R talk"

The probit link function results in

$$p_i = \Phi\big(\beta_0 + \sum_{k=1}^{p} \beta_k x_{ik}\big).$$

Therefore, $P(y_i = 1)$ is viewed as the probability of a standard normal variable being less than $\beta_0 + \sum_{k=1}^{p} \beta_k x_{ik}$.

pops up a lot in clustered data

Probit regression has a very attractive latent variable (i.e., unobserved) interpretation. Let Z_i denote a latent variable associated with each binary outcome.

covariates change the mean of a latent ("hidden") variable

$$Z_i \overset{ind}{\sim} N(\beta_0 + \sum_{k=1}^{p} \beta_k x_{ik},\ 1).$$

Then

$$P(Z_i > 0) = 1 - P(Z_i < 0) = 1 - P\left(\frac{0 - (\beta_0 + \sum_{k=1}^{p} \beta_k x_{ik})}{1} < 0\right)$$

$$= 1 - \Phi\big(-(\beta_0 + \sum_{k=1}^{p} \beta_k x_{ik})\big) = \Phi(\beta_0 + \sum_{k=1}^{p} \beta_k x_{ik}).$$

32/52 M3: GLMs

Probit Regression: Latent Variable Representation

We can rewrite

$$y_i \overset{ind}{\sim} \text{Bernoulli}\ (p_i) \qquad \Phi^{-1}(p_i) = \beta_0 + \sum_{k=1}^{p} \beta_k x_{ik}$$

as a hierarchical model:

capital A for Anova is correct car :: Anova (fit)

$$1.\ Z_i \overset{ind}{\sim} N\big(\beta_0 + \sum_{k=1}^{p} \beta_k x_{ik}, 1\big)$$

$$2.\ y_i = \begin{cases} 0 & \text{if } Z_i < 0 \\ 1 & \text{if } Z_i > 0 \end{cases}$$

Therefore we assume the binary outcome $y_i = 1$ when its latent variable Z_i passes the threshold 0.

The probability of this occurring depends on the mean of the latent variable Z_i. Larger mean $(\beta_0 + \sum_{k=1}^{p} \beta_k x_{ik})$ increases the the probability of $y_i = 1$.

33/52 M3: GLMs

Probit Regression: Interpretation

Consider a simple probit model with only one predictor:

$$y_i \overset{ind}{\sim} \text{Bernoulli}\ (p_i)$$
$$p_i = \Phi(\beta_0 + \beta_1 x_i).$$

Interpretation of the regression coefficients is arguably more challenging. Represents change in z-score.

less easy to interpret than logistic

- The baseline probability is $\Phi(\beta_0)$.
- The effect of a unit increase in x_i on $P(y_i = 1)$ is

$$\Phi(\beta_0 + \beta_1 x_i + \beta_1) - \Phi(\beta_0 + \beta_1 x_i),$$

which again depends on the value of x_i.

Note: e^{β_1} is not an odds ratio in probit

34/52 M3: GLMs

Comparing the logistic and probit regression model, we note the regression coefficients are qualitatively similar but the magnitude differs.

coefficients changed

38/52 M3: GLMs

Poisson Regression

A Poisson regression is specified as follows. For $i = 1, \ldots, n$,

since counts, these are positive integers

$$y_i \overset{ind}{\sim} \text{Poisson}\ (\lambda_i)$$

Equivalently, ~ Pois(E(yi))

$$\log(\lambda_i) = \beta_0 + \sum_{k=1}^{p} \beta_k x_{ik}.$$

For a Poisson distributed random variable,

$$E\, y_i = \lambda_i,$$

$$V\, y_i = \lambda_i$$

This is a very strong assumption, almost never holds!

$$P(y_i = m) = \frac{\lambda_i^m e^{-\lambda_i}}{m!}$$

Poisson regression is often used to model count data. Examples include daily mortality in a city, number of HIV infected individuals in a neighborhood, and number of medical errors at a hospital.

- Here the link function is $\log(\cdot)$.
- $\log(\cdot)$ has domain $(0, \infty)$ and range $(-\infty, \infty)$, and is strictly increasing.

be log

39/52 M3: GLMs

Poisson Regression Interpretation

Consider a simple Poisson regression model with only one covariate:

$$y_i \overset{ind}{\sim} \text{Poisson}\ (\lambda_i)$$

$$\log(\lambda_i) = \beta_0 + \beta_1 x_i.$$

When $x_i = 0$, $\log(\lambda_i) = \beta_0$.

- $e^{\beta_0} = \lambda_i$ is the baseline expected counts.

one covariate to start

λ_i: rate

40/52 M3: GLMs

Poisson Regression Interpretation

Now consider a unit change in x

$$\log(\lambda_i) = \beta_0 + \beta_1 x_i \qquad \log(\lambda_i^*) = \beta_0 + \beta_1 (x_i + 1).$$

Note that

ratio of two rates

$$\beta_1 = \log(\lambda_i^*) - \log(\lambda_i)$$

- $e^{\beta_1} = \lambda_i^*/\lambda_i$ is the relative change in count per unit change in x. Also called the relative rate. Also called the incident rate ratio.
- For continuous variables with $\beta_1 > 0$, the rate increases by $100 * (e^{\beta_1} - 1)\%$ for every unit increase in x.
- For factors with $\beta_j > 0$, the rate increases by $100 * (e^{\beta_j} - 1)\%$ for level j relative to baseline.

here is the interpretation

Covariate impacts are multiplicative rather than additive (applies to log models in general) on the count scale:

Poisson interpretation:

$y_i \overset{IND}{\sim} \text{Pois}(\lambda_i)$

$\log \lambda_i = \beta_0 + \beta_1 x_i$??

$\log(\lambda_i^*) = \beta_0 + \beta_1 (x_i + 1)$

$\log(\lambda_i) = \beta_0 + \beta_1 x_i$

Percentage change formula:

- For factors with $\beta_j > 0$, the rate increases by $100 * (e^{\beta_j} - 1)\%$ for level j relative to baseline.

Covariate impacts are multiplicative rather than additive (applies to log models in general) on the count scale:

$$E\, y_i = e^{\beta_0} e^{\beta_1 x_{i1}} \dots e^{\beta_p x_{ip}}$$

41/52 M3: GLMs

Percentage change formula:

$$100\left(\frac{\lambda_i^* - \lambda_i}{\lambda_i}\right) =$$

$$100\left(\frac{e^{\beta_0 + \beta_1 (x_i + 1)} - e^{\beta_0 + \beta_1 x_i}}{e^{\beta_0 + \beta_1 x_i}}\right)$$

$$100\left(e^{\beta_1} - 1\right)$$

Example: bacteria counts

where mean = var is true

Dataset: antibiotic resistance in a mutation of *E. coli*.

Variables:

- *Colony*: the number of ampicillin-resistant mutant colonies → response var y_i
- *Conc*: the concentration of novobiocin (μg/ml)
- *Media*: the type of media used for bacterial growth.

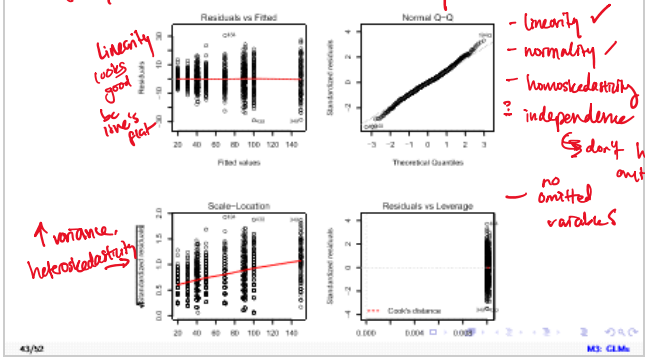
The experiment involved two media preparations (LB and M9), 5 concentrations of novobiocin, and 100 replicates for each media-concentration combination. TNTC (too numerous to count) were recorded when the number of colonies exceeded 300.

42/52 M3: GLMs

Modeling count data

```
lm_colony = lm(Colony_numeric~factor(Conc)*Media,data=colonydata)
```

First, try linear model (normal error)



linearity looks good by line's plot

normality some deviation at ends

- linearity ✓
- normality ✓
- homoskedasticity ✗
- ? independence

don't have anything for this

- no omitted variables

↑ variance, heteroskedasticity

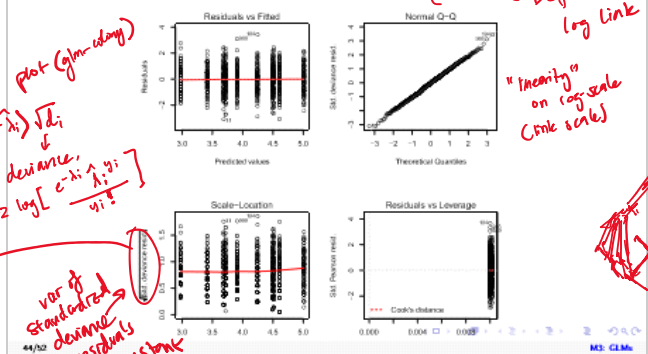
43/52 M3: GLMs

Modeling count data: Poisson

```
glm_colony = glm(Colony_numeric~factor(Conc)*Media,data=colonydata,family = "poisson")
```

Defaults to log link

now assessing standardized deviance residuals? Normality of standardized deviance residuals



plot(glm_colony)

"linearity" on log scale (link scale)

$e_i^* = \text{sign}(y_i - \hat{\lambda}_i)\sqrt{d_i}$

deviance, $-2 \log\left[\frac{e^{-\hat{\lambda}_i}\hat{\lambda}_i^{y_i}}{y_i!}\right]$

transformation such that standardized deviance resids should be approx standard normal

var of standardized deviance residuals constant

44/52 M3: GLMs

Residuals in glms

The usual plot of residual versus fitted is not useful in GLMs because of the relationship between the mean and variance.

approx standard normal

Residuals in glms

The usual plot of residual versus fitted is not useful in GLMs because of the relationship between the mean and variance.

The deviance residuals have an approximate normal distribution.

The deviance residual is

$\hat{\lambda}_i$ (he changed notation)

$$\hat{\epsilon}_i^d = \text{sign}(y_i - \hat{\mu}_i)\sqrt{d_i}.$$

where d_i is the ith term in the calculation of the deviance. For details, see p.113 in Wood 2017. (This plot is not useful for 0/1 data as common in logistic regression.)

teach me french pls

Goodness of fit tests, quasipoisson

In glms, the deviance performs a role similar to the sum of squared errors in OLS:

(log likelihood)

$$D(\hat{\beta}) = 2\left\{\ell(\hat{\beta}_{\max};\mathbf{y}) - \ell(\hat{\beta};\mathbf{y})\right\}$$

where $\ell(\hat{\beta}_{\max};\mathbf{y})$ is the "saturated model," equal to likelihood evaluated at $\hat{\mu}_i = y_i$. ($E(y_i) = y_i$)

Asymptotically, $D(\hat{\beta}) \sim \chi^2_{n-p}$ (chi-squared distr. w/ n-p df)

One can perform a deviance test to examine goodness of fit. The null hypothesis is that the model fits the data. $p < 0.05$ indicates a problem (i.e., lack of fit). (null: model adequately fits data)

```
with(glm_colony, cbind(res.deviance = deviance, df = df.residual,
p = pchisq(deviance, df.residual, lower.tail=FALSE)))

res.deviance  df         p
[1,]     973.8841 987 0.6108368
```

fail to reject null, the model adequately fits

So a non-significant pvalue is GOOD

Here, $p > 0.05$, from which we conclude that the model provides an adequate fit.

Overdispersion

In Poisson, the assumption that $E(y_i) = V(y_i)$ is often violated. (same as var(y_i), he got lazy)

One can add an additional overdispersion parameter, also called a scale parameter.

One can adjust the parameter variances by the scale parameter:

Under null:

$$\hat{\beta} \sim N(0, I(\beta)^{-1}\phi)$$

(ϕ: scale variance to account for violations of assumption on relationship between mean & variance; $I(\beta)$: usual Fisher information)

We will see this again in GEEs.

Section 3.1.5 in Wood describes three different estimators of ϕ.

Quasipoisson in GLM

family = "quasi poisson"

```
> glm_colony_quasi = glm(Colony_numeric~factor(Conc)+Media,data=colonydata,family = "quasi
> summary(glm_colony_quasi)

Call:
glm(formula = Colony_numeric ~ factor(Conc) * Media, family = "quasipoisson",
    data = colonydata)

Deviance Residuals:
    Min       1Q   Median       3Q      Max
-3.0815  -0.7615  -0.0047   0.6573   3.4344

Coefficients:
                       Estimate Std. Error t value Pr(>|t|)
(Intercept)            3.683308   0.015807 233.023  < 2e-16 ***

slight underdispersion but close enough to usual, only worry about overdispersion

48/52 M3: GLMs

Back to original model

When the data are slightly underdispersed, i.e., dispersion parameter<1, and there is no evidence of lack of fit, I suggest using the original model:

```
> summary(glm_colony)

Call:
glm(formula = Colony_numeric ~ factor(Conc) * Media, family = "poisson",
    data = colonydata)

Deviance Residuals:
    Min       1Q   Median       3Q      Max
-3.0815  -0.7615  -0.0047   0.6573   3.4344

Coefficients:
                         Estimate Std. Error z value Pr(>|z|)
(Intercept)              3.683308   0.015935 231.140  < 2e-16 ***
factor(Conc)100          0.557587   0.019947  27.953  < 2e-16 ***

```

identical between Poisson & Quasipoisson

49/52 M3: GLMs

Interpretation

- The rate here is colonies per petri dish (for some fixed amount of time).
- Intercept: the log of the expected count is 3.68 in LB media with no novobiocin. Equivalently, the log rate is 3.68 in LB media with no novobiocin.
- The estimated number of colonies and 95% CI for this baseline is $e^{3.68}$, $(e^{3.68-1.96*0.016}, e^{3.68+1.96(0.016)}) = 39.6\ (38.4, 41)$.
- The multiplicative effect of the interaction between M9 and 300 is $e^{0.009}$, i.e., the rate increases by 0.9% relative to no interaction, which is not significant ($p > 0.05$).
- More on M9 with 300: ratio of counts in M9 300 to counts in M9 with no novobiocin:
  $e^{3.68+0.92-0.71+0.009}/e^{3.68-0.71} = e^{0.92+0.009} = 2.5.$

↳ 2.5x as many colonies compared to M9 300 relative to M9 with no novobiocin

50/52 M3: GLMs

Example with overdispersion

For educational purposes, consider this poor fitting model:

```
> glm_nomedia_quasi = glm(Colony_numeric~factor(Conc),data=colonydata,
family = "quasipoisson")
> summary(glm_nomedia_quasi)
Call:
glm(formula = Colony_numeric ~ factor(Conc), family = "quasipoisson",
    data = colonydata)

Deviance Residuals:
    Min       1Q   Median       3Q      Max
-5.6832  -2.8772  -0.2983   2.5557   6.2330

Coefficients:
             Estimate Std. Error t value Pr(>|t|)
(Intercept)   3.38805    0.03727   90.90   <2e-16 ***
factor(Conc)100  0.52177   0.04701   11.10   <2e-16 ***
